WHERE DISCOVERIES BEGIN

What is beamstrahlung

- The radiation of the particles of one beam due to the bending force of the EM field of the other beam
- Many similarities with SR but
- Also some substantial differences due to very short “magnet” ($L = \sigma_z / 2\sqrt{2}$), very strong magnet (3000T at the ILC). Short magnets produce a much broader angular distribution

Beam-beam interaction (BBI) d.o.f. (gaussian approximation)

BBI d.o.f. counting at the ILC

- 7 gaussian transverse d.o.f.
- 2 beam lengths
- At least 4 wake field parameters, and possibly 2 longitudinal
- Total 13-15 BBC parameters that may affect the luminosity

Other possible BBI detectors

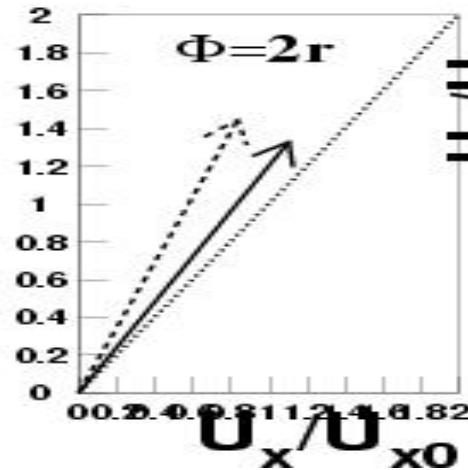

- Beam-beam deflection via BPMs. Limited to 2 quantities by Newton's 3rd law. Semi-passive device.
- Gamma ray beamstrahlung monitor. Almost certainly a powerful device if it can be built with enough pixels, interferes with the beam dump (340kW is dissipated in the dump). It observes at least the total radiation, the centroid of the radiation, and the angular spread (10 d.o.f.)
- Pairs spectrometer (10^5 per BBI). Probably little information as directionality of pair is lost.

Properties of large angle radiation

- It corresponds to the near backward direction in electron rest frame (5 degrees at CESR, 2-4 degrees at KEKB)
- Lorentz transformation of EM field produces a 8-fold pattern, unpolarized as whole, but locally up to 100% polarized according to $\cos^2(2\phi)$, $\sin^2(2\phi)$

Some examples of Large Angle BMST pattern recognition

Large angle beamstrahlung power

- Total energy for perfect collision by beam 1 is:
 $P_0 = 0.11 \gamma^2 r_e^3 m c^2 N_1 N_2^2 / (\sigma_x^2 \sigma_z)$
- Wider angular distribution (compared to quadrupole SR) provides main background separation
- CESR regime: exponent is about 4.5
- ILC regime: exponent is very small

$$\frac{d^2 I}{d\Omega d\omega} = \frac{3\sigma_z}{4c\pi\sqrt{\pi}} P_0 \frac{1}{\gamma^4 \theta^4} \exp\left(\frac{-\omega^2 \theta^4 \sigma_z^2}{16c^2}\right)$$

Short magnet approximation for the background (quadrupoles)

If the angle can be considered large and constant...

- Assuming $(\text{atan}(z/\delta) + \text{atan}((L-z)/\delta))$ as the field profile, one gets $(u = \gamma\theta, s, c = \cos, \sin(\phi))$

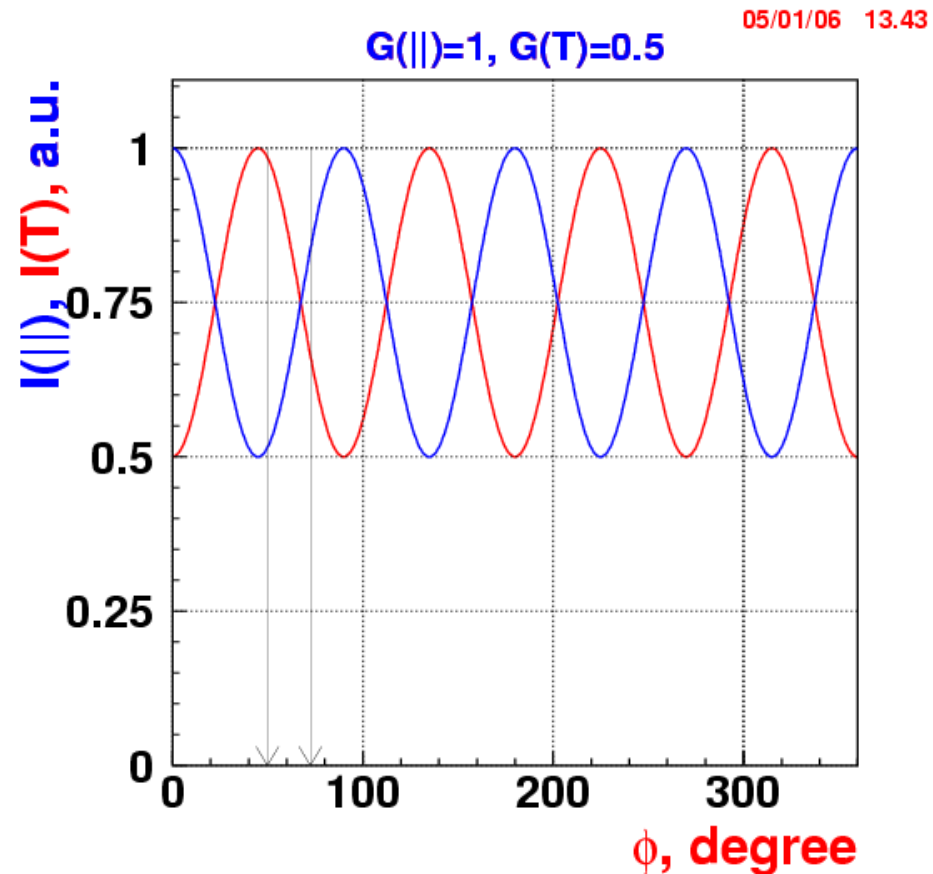

$$\frac{d^2P}{d\Omega d\omega} \propto \frac{(1-u^2)^2 + (su)^2}{(1+u^2)^6} \frac{1}{\omega^2} \exp(i\omega\theta/c)$$

With a short magnet MC for the quadrupoles...

- The observed radiation is expected to be very red (IR/VIS of order one, 0.02 observed)
- The observed radiation is expected to have a polarization of order several (1.5-3 observed)
- The predicted radiation for a 5σ HEP simulation and sharp acceptance is exactly zero.
- The backgrounds have a predominant contribution from the halo, which we have just started to describe

Large Angle Detector Concept

- Radiated power for horizontal and vertical polarizations
 - Two optic ports are reserved for each direction (E and W)
 - IR PMT for signal, VIS PMT for background

CESR location

Beam pipe and primary mirror

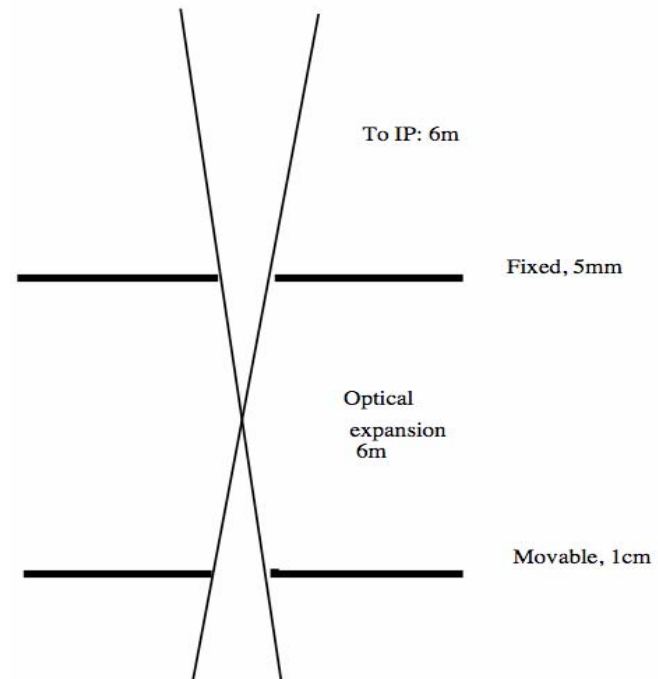

1/4 Set-up principal scheme

- Transverse view
- Optic channel
- Mirrors
- PBS
- Chromatic mirrors
- PMT numeration

Detector parameters of interest

- Diffraction limit is 0.1 mrad. Sharp cutoff can be assumed
- Optics is double collimator. Has triangular acceptance with max width of 1.7mrad
- At IP, accepted spot is about 1cm

Set-up general view

- East side of CLEO
- Mirrors and optic port
~6m apart from I.P.
- Optic channel with
wide band mirrors

On the top of set-up

- Input optics channel
- Radiation profile scanner
- Optics path extension volume

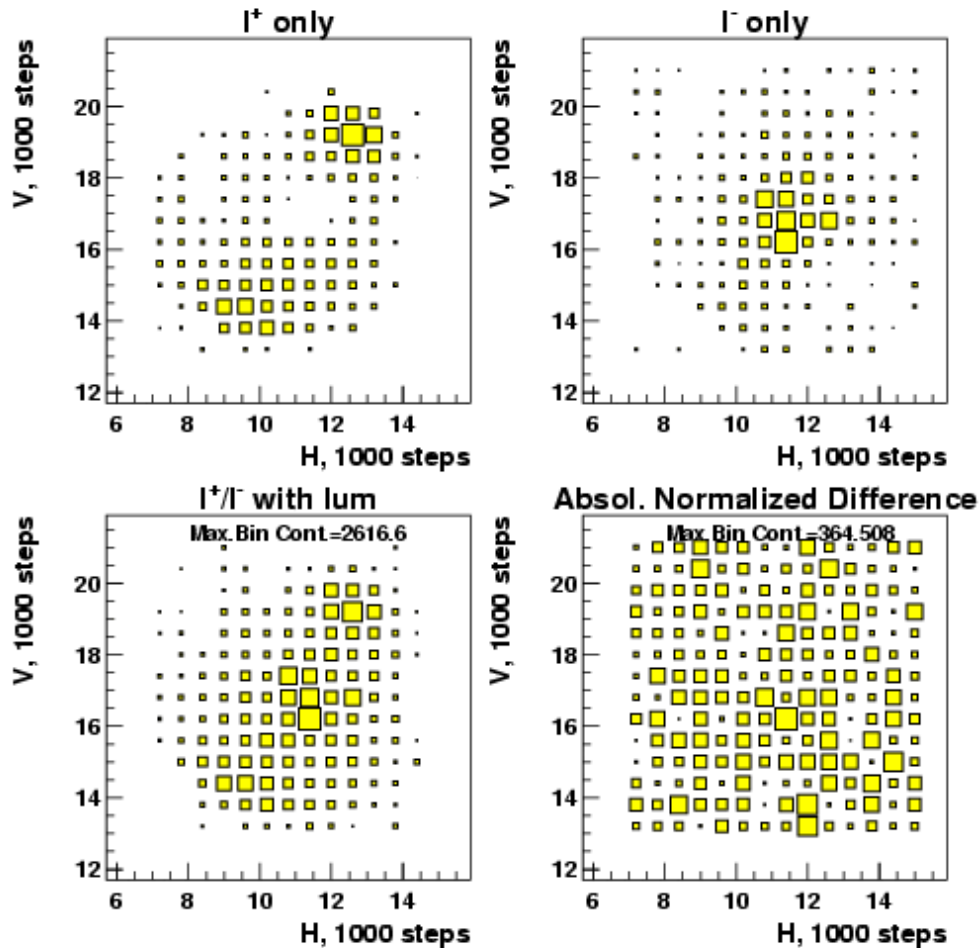

The $\frac{1}{4}$ detector

- Input channel
- Polarizing Beam Splitter
- Dichroic filters
- PMT's assembly
- Cooling...

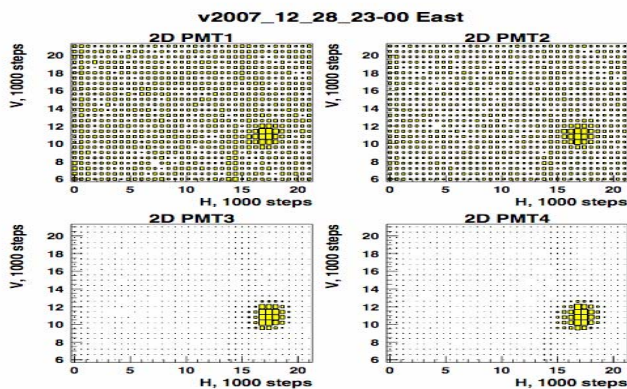

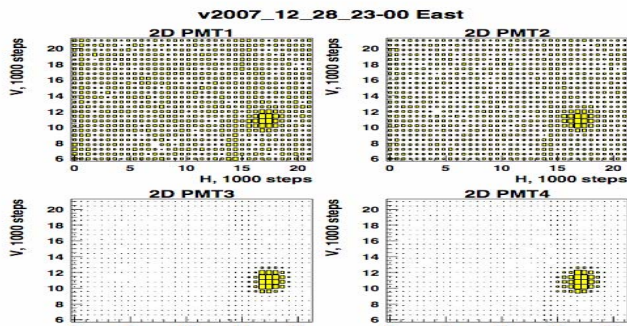

Check for alignment @ 4.2GeV

Subtraction procedure. $E_0=4.2\text{GeV}$, July 30, 2002

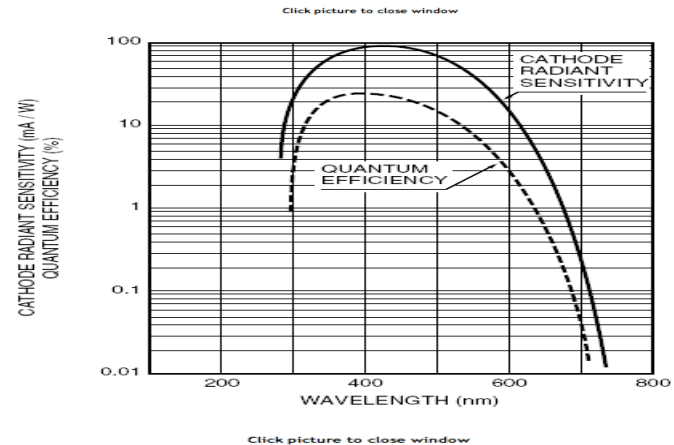

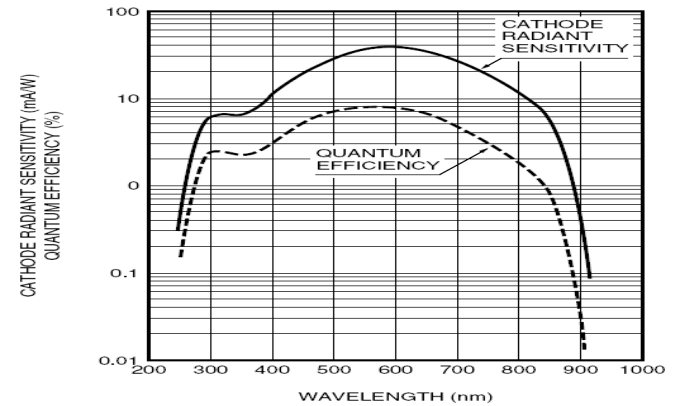

Directionality

- Scanning is routinely done to reconfirm the centroid of the luminous spot.

Photomultipliers

- IR: R2228, has relatively high noise (3-5 kHz). Has filter at 775 nm
- VIS: R6095, almost noise-free, has no filter
- Previous IR PMTs R-316-02 were discontinued

PMT rate correlations with beam currents

Typical rates

- At HEP conditions, VIS PMTs (West) will have a rate of about 300kHz (0.1Hz channels are used) and IR PMTs about 6kHz.
- In the East, 60kHz and 2kHz.
- Expected BMST rates are about 500Hz at the nominal theta

Detector systematics detail

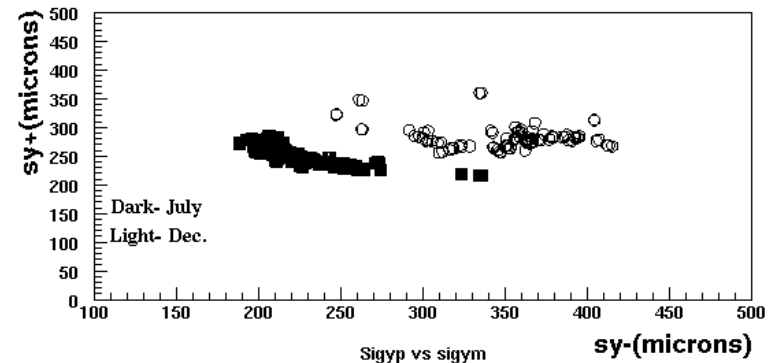

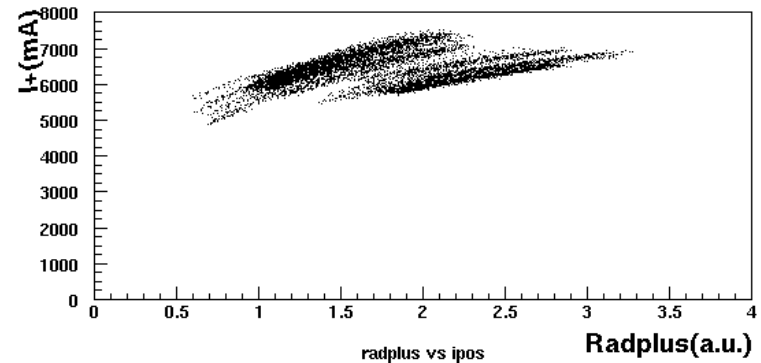

- Flashlight calibration measures all relative efficiencies to about 0.3%. Absolute efficiencies of VIS PMT >90%, optical channels assumed to be 75±25%.
- Recurrent electronic noise problems on East side (electrons)
- Two major data taking periods in July and December 2007 (about 120 good fills each), with dark noise measured every 8 hours.

Data analysis method

- The signal sought ought to increase IR light w.r.t. VIS light when a strong beam is opposite, so
$$\text{IR}/\text{VIS} = k_1 + k_2 I_{\text{oppo}}^2$$
- The method also takes into account possible small variations of the bkg through normalization with VIS light
- The expected signal in VIS light is of the order of 10^{-4} of the rate and can be safely ignored
- Runs are minimally selected (continuous beams for at least 600 seconds) with chi square and dark noise (cleaning) cuts later to take care of noisy ones

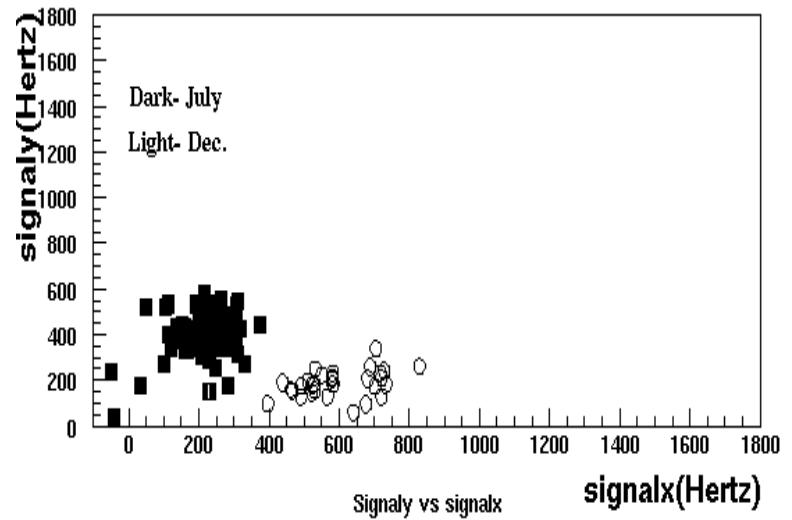

Natural variability of machine provided crucial evidence

- In July, relatively high e^+ current and relatively low e^- current. In December, currents are more balanced, providing a stronger expected BMST signal
- In July, e^- beam was smaller than e^+ . In December, the reverse was true. Differing polarizations expected

Main results page

- Signal(x) strongly correlated to $I_+ I_-^2$
- Signal strongly polarized according to ratios of vertical sigmas
- Total rates consistent with expectations at 10.3 mrad

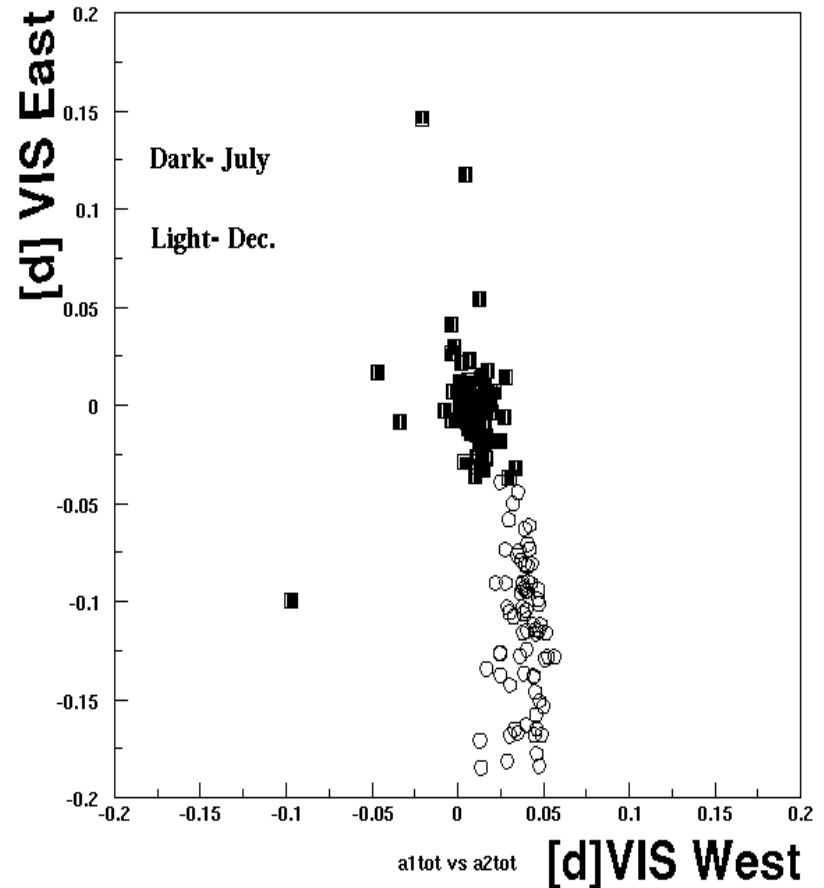

What went wrong

- The beams ended up being longer than design
- The primary mirrors are attached to the beam pipe. We found a best correction of -0.2mrad for the West PMTs and +1.1mrad for the East (using VIS only). This virtually killed the East signal
- The tails of the beam decrease in intensity during a fill

What went wrong (II)

- The fractional tails of a beam will typically decline during a shift
- The decline much more pronounced in the East (electrons) due to larger BBI, wider beam, larger angle, and bunch length

Large East distortions related to a number of variables

Where we are

- We have been able to explain qualitatively ALL the effects seen in our apparatus
- ALL major cross checks on the signal are successful. In particular, polarization effects appear to be proven
- We are currently trying to establish the beam tail characterization using only the VIS data
- Followed by one big global fit (including bunch length, σ_x , crossing angle, etc.)
- Publication of NIM and PRSTAB papers

Summary

- The first generation Large Angle Beamstrahlung detector was successful, but...
- This technique is dominated by systematic errors, therefore its only figure of merit is S/B
- In order to make this technique into a useful monitor, three conditions must be met:
 - - $S/B \gg 1$ (it was 0.03-0.06 at CESR). We can tolerate lower S/B if the tails are proven to be constant during a fill
 - - Much more beam data acquired
 - A device that can monitor the beam halo directly

Signal and background at KEKB

- KEKB is the best place where to pursue this technique further, due to short bunch length
- Signal at KEK (assume 10 mrad observation): the signal scales with $(N^3/\gamma^2\sigma_x^2\sigma_z)*\exp(-(\pi\sigma_z\theta^2/2\lambda)^2)$ - about 100 times higher specific signal
- The halo, assuming to be dominated by the BBI, scales like (N/γ) - close to CESR values. If it is dominated by the residual gas pressure, it should be much more constant and therefore subtractable
- Other improvements at KEK (cmp to CESR): beams cross quadrupoles near axis (less background), there is no parasitic BBI, and therefore no shifts in the crossing angle

What information would have been useful

- Fringe map of quads
- BPMs
- Background/pressure monitors
- σ_x and σ_z from CLEO directly in the database

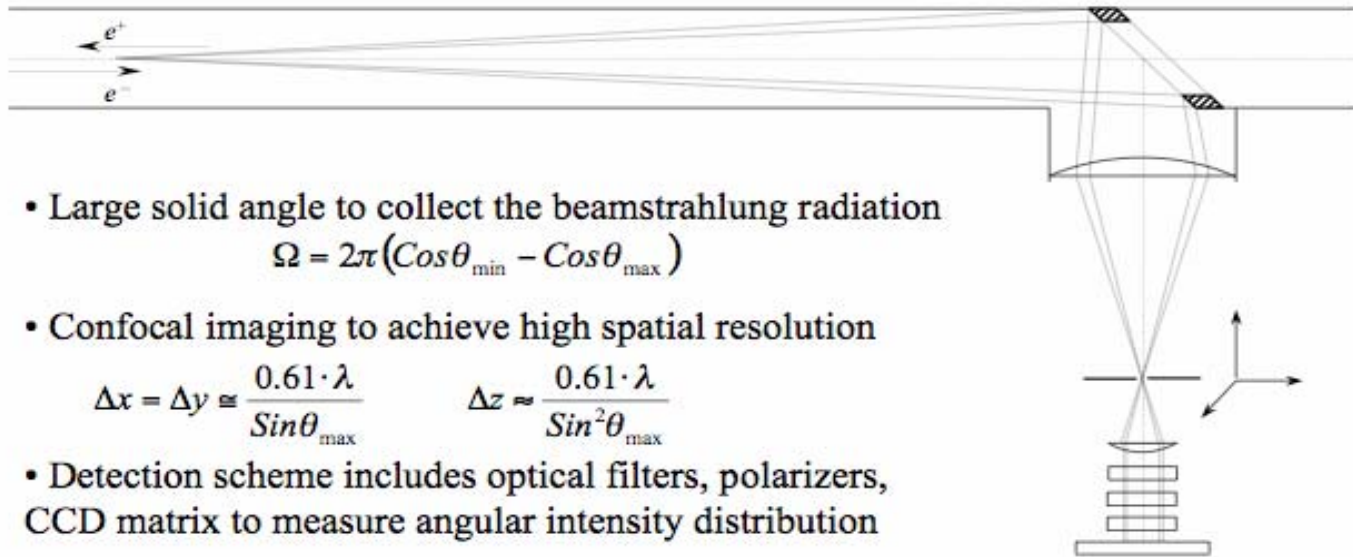

KEKB concept for the detector

- 2 viewports at ± 90 degrees: minimal backgrounds, insensitive of beam motion, insensitive of beam pipe alignment
- Look at radiation in 4 or more bands: e.g., $\lambda < 350\text{nm}$, $400\text{nm} < \lambda < 450\text{nm}$, $500\text{nm} < \lambda < 550\text{nm}$, $600\text{nm} < \lambda < 650\text{nm}$
- (this is assuming one uses only PMTs R6095)

ILC concept (I)

Hollow mirror imaging system for detection of beamstrahlung radiation

- Large solid angle to collect the beamstrahlung radiation

$$\Omega = 2\pi(\cos\theta_{\min} - \cos\theta_{\max})$$

- Confocal imaging to achieve high spatial resolution

$$\Delta x = \Delta y \cong \frac{0.61 \cdot \lambda}{\sin\theta_{\max}} \quad \Delta z \approx \frac{0.61 \cdot \lambda}{\sin^2\theta_{\max}}$$

- Detection scheme includes optical filters, polarizers, CCD matrix to measure angular intensity distribution

ILC Concept (II)

- Rates per bunch crossing ($1 < \theta < 2 \text{ mrad}$): about 20000 at nominal conditions
- Σ_y' is about 0.01 mrad at the ILC. Tails unknown
- Rates per bunch cross, ($5 < \theta < 6 \text{ mrad}$): about 80 at nominal conditions
- Backgrounds should be very close to zero at this angle

Coherent beamstrahlung

Beam pipe shielding

- Beam pipe effects are important for long magnets (Heifets, Mikhailichenko, SLAC-AP-083)

$$\sigma_z < \lambda < d \sqrt{d / R}$$

- However at the ILC R is of order 0.5 meters and coherent radiation will be present in the millimeter range

Can we see this effect at current accelerators?

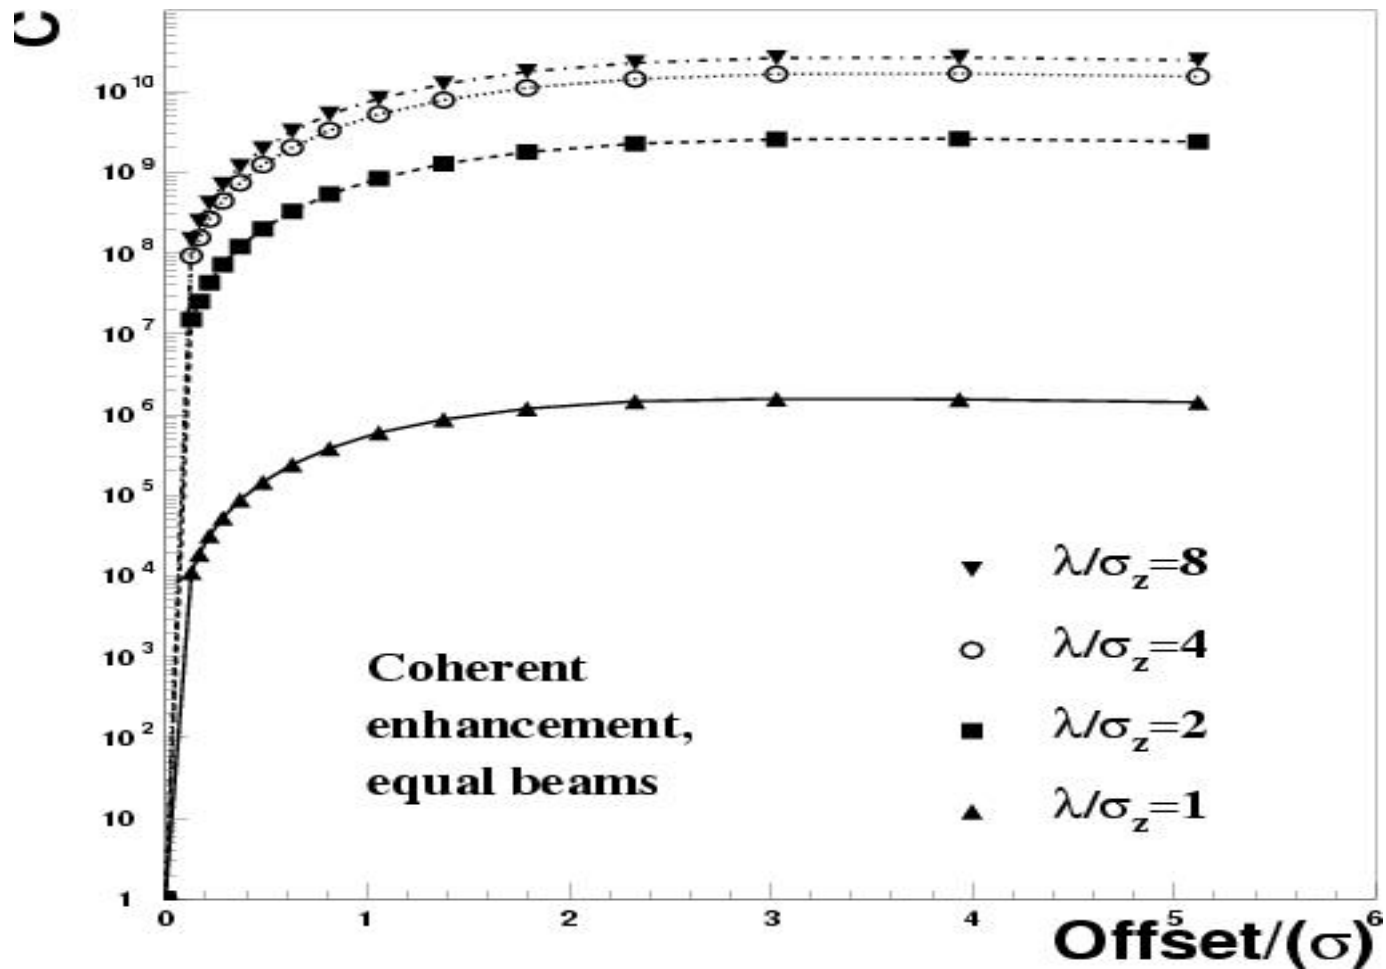

- The best place is KEKB ($d=3\text{cm}$, $\sigma_z=6\text{mm}$)
- But, need the fraction of coherent power generated within the beam pipe. Fortunately, a paper by Hoffstatter, Sagan et al. (not yet published) has produced a code to calculate just that
- Try to detect TM waveguide modes at first BPM (M. Billings) with single bunches offset by $4\sigma_y$. Time, frequency, beam-beam offset and N^4 signatures available

· Conclusions

- Large angle Beamstrahlung seen at CESR
- Its main features confirmed
- Major sources of systematics found
- Interesting for ILC R&D in an area of strong need

Backup slides

Coherent enhancement at the ILC (dynamic beams, complete coherence)

C

CB coherent enhancement (vacuum, no angular divergence)

- $C = P(\text{CB}) / P(\text{IB})$
- $C(\lambda, \Omega) = N \exp(-(2\pi\sigma_z / \lambda)^2)$ (G. Bonvicini, unpublished)
- Angular effects reduce radiation by $O((\theta_{\text{div}} / \theta_{\text{rad}})^2)$ (not important at CESR, factor of 100 at the ILC). This gives a maximum CB average power at the ILC in the neighborhood of 1W (0.1GW peak)

IB power (stiff beams)

$$P_1(d) \approx 0.1 \frac{N_1 N_2^2}{\sigma_x^2 \sigma_z} \gamma^2 m c^2 r_e^3 (g_x(d) + g_y(d))$$

- CB largely leaves the spectrum unaffected and adds a factor N_1

Coherent beamstrahlung

- Coherent synchrotron radiation has been observed many times for very short beams
- Coherence condition is $\lambda > \sigma_z$ (there is also a transverse coherence condition, negligible here)
- A similar situation arises when beams are separated - coherent beamstrahlung
- Coherent enhancement always proportional to N
